the background. Then the chemist places the compound (sample) into the beam and obtains the spectrum resulting from the Fourier transform of the interferogram. This spectrum contains absorption bands for both the compound and the background. The computer software automatically subtracts the spectrum of the background from the sample spectrum, yielding the spectrum of the compound being analyzed. The subtracted spectrum is essentially identical to that obtained from a traditional double-beam dispersive instrument. See Section 2.22 for more detailed information about the background spectrum.

### 2.6 PREPARATION OF SAMPLES FOR INFRARED SPECTROSCOPY

To determine the infrared spectrum of a compound, one must place the compound in a sample holder, or cell. In infrared spectroscopy, this immediately poses a problem. Glass and plastics absorb strongly throughout the infrared region of the spectrum. Cells must be constructed of ionic substances—typically sodium chloride or potassium bromide. Potassium bromide plates are more expensive than sodium chloride plates but have the advantage of usefulness in the range of 4000 to 400 cm\(^{-1}\). Sodium chloride plates are used widely because of their relatively low cost. The practical range for their use in spectroscopy extends from 4000 to 650 cm\(^{-1}\). Sodium chloride begins to absorb at 650 cm\(^{-1}\), and any bands with frequencies less than this value will not be observed. Since few important bands appear below 650 cm\(^{-1}\), sodium chloride plates are in most common use for routine infrared spectroscopy.

**Liquids.** A drop of a liquid organic compound is placed between a pair of polished sodium chloride or potassium bromide plates, referred to as salt plates. When the plates are squeezed gently, a thin liquid film forms between them. A spectrum determined by this method is referred to as a neat spectrum since no solvent is used. Salt plates break easily and are water soluble. Organic compounds analyzed by this technique must be free of water. The pair of plates is inserted into a holder that fits into the spectrometer.

**Solids.** There are at least three common methods for preparing a solid sample for spectroscopy. The first method involves mixing the finely ground solid sample with powdered potassium bromide and pressing the mixture under high pressure. Under pressure, the potassium bromide melts and seals the compound into a matrix. The result is a KBr pellet that can be inserted into a holder in the spectrometer. The main disadvantage of this method is that potassium bromide absorbs water, which may interfere with the spectrum that is obtained. If a good pellet is prepared, the spectrum obtained will have no interfering bands since potassium bromide is transparent down to 400 cm\(^{-1}\).

The second method, a Nujol mull, involves grinding the compound with mineral oil (Nujol) to create a suspension of the finely ground sample dispersed in the mineral oil. The thick suspension is placed between salt plates. The main disadvantage of this method is that the mineral oil obscures bands that may be present in the analyzed compound. Nujol bands appear at 2924, 1462, and 1377 cm\(^{-1}\) (p. 32).

The third common method used with solids is to dissolve the organic compound in a solvent, most commonly carbon tetrachloride (CCl\(_4\)). Again, as was the case with mineral oil, some regions of the spectrum are obscured by bands in the solvent. Although it is possible to cancel out the solvent from the spectrum by computer or instrumental techniques, the region around 785 cm\(^{-1}\) is often obscured by the strong C–Cl stretch that occurs there.

### 2.7 WHAT TO LOOK FOR WHEN EXAMINING INFRARED SPECTRA

An infrared spectrometer determines the positions and relative sizes of all the absorptions, or peaks, in the infrared region and plots them on a piece of paper. This plot of absorption intensity versus wavenumber (or sometimes wavelength) is referred to as the infrared spectrum of the compound.
2.7 What to Look for When Examining Infrared Spectra

Figure 2.4 shows a typical infrared spectrum, that of 3-methyl-2-butanone. The spectrum exhibits at least two strongly absorbing peaks at about 3000 and 1715 cm\(^{-1}\) for the C–H and C=O stretching frequencies, respectively.

The strong absorption at 1715 cm\(^{-1}\) that corresponds to the carbonyl group (C=O) is quite intense. In addition to the characteristic position of absorption, the *shape* and *intensity* of this peak are also unique to the C=O bond. This is true for almost every type of absorption peak; both shape and intensity characteristics can be described, and these characteristics often enable the chemist to distinguish the peak in potentially confusing situations. For instance, to some extent C=O and C=C bonds absorb in the same region of the infrared spectrum:

\[
\begin{align*}
C=O & \quad 1850–1630 \text{ cm}^{-1} \\
C=C & \quad 1680–1620 \text{ cm}^{-1}
\end{align*}
\]

However, the C=O bond is a strong absorber, whereas the C=C bond generally absorbs only weakly (Fig. 2.5). Hence, trained observers would not interpret a strong peak at 1670 cm\(^{-1}\) to be a C=C double bond or a weak absorption at this frequency to be due to a carbonyl group.

The shape and fine structure of a peak often give clues to its identity as well. Thus, although the N–H and O–H regions overlap,

\[
\begin{align*}
O–H & \quad 3650–3200 \text{ cm}^{-1} \\
N–H & \quad 3500–3300 \text{ cm}^{-1}
\end{align*}
\]

**Figure 2.4** The infrared spectrum of 3-methyl-2-butanone (neat liquid, KBr plates).

**Figure 2.5** A comparison of the intensities of the C=O and C=C absorption bands.
the N–H absorption usually has one or two sharp absorption bands of lower intensity, whereas O–H, when it is in the N–H region, usually gives a broad absorption peak. Also, primary amines give two absorptions in this region, whereas alcohols as pure liquids give only one (Fig. 2.6). Figure 2.6 also shows typical patterns for the C–H stretching frequencies at about 3000 cm\(^{-1}\).

Therefore, while you study the sample spectra in the pages that follow, take notice of shapes and intensities. They are as important as the frequency at which an absorption occurs, and the eye must be trained to recognize these features. Often, when reading the literature of organic chemistry, you will find absorptions referred to as strong (s), medium (m), weak (w), broad, or sharp. The author is trying to convey some idea of what the peak looks like without actually drawing the spectrum.

### 2.8 Correlation Charts and Tables

To extract structural information from infrared spectra, you must be familiar with the frequencies at which various functional groups absorb. You may consult infrared correlation tables, which provide as much information as is known about where the various functional groups absorb. The references listed at the end of this chapter contain extensive series of correlation tables. Sometimes, the absorption information is presented in the form of a chart called a correlation chart. Table 2.3 is a simplified correlation table; a more detailed chart appears in Appendix 1.

The volume of data in Table 2.3 looks as though it may be difficult to assimilate. However, it is really quite easy if you start simply and then slowly increase your familiarity with and ability to interpret the finer details of an infrared spectrum. You can do this most easily by first establishing the broad visual patterns of Figure 2.2 quite firmly in mind. Then, as a second step, memorize a “typical absorption value”—a single number that can be used as a pivotal value—for each of the functional groups in this pattern. For example, start with a simple aliphatic ketone as a model for all typical carbonyl compounds. The typical aliphatic ketone has a carbonyl absorption of about 1715 ± 10 cm\(^{-1}\). Without worrying about the variation, memorize 1715 cm\(^{-1}\) as the base value for carbonyl absorption. Then, more slowly, familiarize yourself with the extent of the carbonyl range and the visual pattern showing where the different kinds of carbonyl groups appear throughout this region. See, for instance, Section 2.14 (p. 52), which gives typical values for the various types of carbonyl compounds. Also, learn how factors such as ring strain and conjugation affect the base values (i.e., in which direction the values are shifted). Learn the trends, always keeping the memorized base value (1715 cm\(^{-1}\)) in mind. As a beginning, it might prove useful to memorize the base values for this approach given in Table 2.4. Notice that there are only eight of them.

2.9 HOW TO APPROACH THE ANALYSIS OF A SPECTRUM (OR WHAT YOU CAN TELL AT A GLANCE)

When analyzing the spectrum of an unknown, concentrate your first efforts on determining the presence (or absence) of a few major functional groups. The C=O, O–H, N–H, C–O, C≡C, C≡N, and NO₂ peaks are the most conspicuous and give immediate structural information if they are present. Do not try to make a detailed analysis of the C–H absorptions near 3000 cm⁻¹; almost all compounds have these absorptions. Do not worry about subtleties of the exact environment in which the functional group is found. Following is a major checklist of the important gross features.

1. Is a carbonyl group present? The C=O group gives rise to a strong absorption in the region 1820–1660 cm⁻¹. The peak is often the strongest in the spectrum and of medium width. You can’t miss it.

2. If C=O is present, check the following types (if it is absent, go to step 3):
   - **ACIDS**
     - Is O–H also present?
     - Broad absorption near 3400–2400 cm⁻¹ (usually overlaps C–H).
   - **AMIDES**
     - Is N–H also present?
     - Medium absorption near 3400 cm⁻¹; sometimes a double peak with equivalent halves.
   - **ESTERS**
     - Is C–O also present?
     - Strong-intensity absorptions near 1300–1000 cm⁻¹.
   - **ANHYDRIDES**
     - Two C=O absorptions near 1810 and 1760 cm⁻¹.
   - **ALDEHYDES**
     - Is aldehyde C–H present?
     - Two weak absorptions near 2850 and 2750 cm⁻¹ on right side of the aliphatic C–H absorptions.
   - **KETONES**
     - The preceding five choices have been eliminated.

3. If C=O is absent:
   - **ALCOHOLS, PHENOLS**
     - Check for O–H.
     - Broad absorption near 3400–3300 cm⁻¹.
     - Confirm this by finding C–O near 1300–1000 cm⁻¹.
   - **AMINES**
     - Check for N–H.
     - Medium absorption(s) near 3400 cm⁻¹.
   - **ETHERS**
     - Check for C–O near 1300–1000 cm⁻¹ (and absence of O–H near 3400 cm⁻¹).
4. Double bonds and/or aromatic rings
   - $\text{C}=$-$\text{C}$ is a weak absorption near 1650 cm$^{-1}$.
   - Medium-to-strong absorptions in the region 1600–1450 cm$^{-1}$; these often imply an aromatic ring.
   - Confirm the double bond or aromatic ring by consulting the $\text{C}=$-$\text{H}$ region; aromatic and vinyl $\text{C}=$-$\text{H}$ occur to the left of 3000 cm$^{-1}$ (aliphatic $\text{C}=$-$\text{H}$ occurs to the right of this value).

5. Triple bonds
   - $\text{C}=$-$\text{N}$ is a medium, sharp absorption near 2250 cm$^{-1}$.
   - $\text{C}=$-$\text{C}$ is a weak, sharp absorption near 2150 cm$^{-1}$.
   - Check also for acetylenic $\text{C}=$-$\text{H}$ near 3300 cm$^{-1}$.

6. Nitro groups
   - Two strong absorptions at 1600–1530 cm$^{-1}$ and 1390–1300 cm$^{-1}$.

7. Hydrocarbons
   - None of the preceding is found.
   - Major absorptions are in $\text{C}=$-$\text{H}$ region near 3000 cm$^{-1}$.
   - Very simple spectrum; the only other absorptions appear near 1460 and 1375 cm$^{-1}$.

The beginning student should resist the idea of trying to assign or interpret every peak in the spectrum. You simply will not be able to do it. Concentrate first on learning these major peaks and recognizing their presence or absence. This is best done by carefully studying the illustrative spectra in the sections that follow.

---

A SURVEY OF THE IMPORTANT FUNCTIONAL GROUPS, WITH EXAMPLES

The following sections describe the behaviors of important functional groups toward infrared radiation. These sections are organized as follows:

1. The basic information about the functional group or type of vibration is abstracted and placed in a Spectral Analysis Box, where it may be consulted easily.
2. Examples of spectra follow the basic section. The major absorptions of diagnostic value are indicated on each spectrum.
3. Following the spectral examples, a discussion section provides details about the functional groups and other information that may be of use in identifying organic compounds.

\[\text{2.10 HYDROCARBONS: ALKANES, ALKENES, AND ALKYNES}\]

\[\text{A. Alkanes}\]

Alkanes show very few absorption bands in the infrared spectrum. They yield four or more $\text{C}=$-$\text{H}$ stretching peaks near 3000 cm$^{-1}$ plus CH$_2$ and CH$_3$ bending peaks in the range 1475–1365 cm$^{-1}$.
ALKANES

The spectrum is usually simple, with few peaks.

C–H Stretch occurs around 3000 cm\(^{-1}\).

In alkanes (except strained ring compounds), \(sp^3\) C–H absorption always occurs at frequencies less than 3000 cm\(^{-1}\) (3000–2840 cm\(^{-1}\)).

If a compound has vinylic, aromatic, acetylenic, or cyclopropyl hydrogens, the C–H absorption is greater than 3000 cm\(^{-1}\). These compounds have \(sp^2\) and \(sp\) hybridizations (see Sections 2.10B and 2.10C).

CH\(_2\) Methylene groups have a characteristic bending absorption of approximately 1465 cm\(^{-1}\).

CH\(_3\) Methyl groups have a characteristic bending absorption of approximately 1375 cm\(^{-1}\).

CH\(_2\) The bending (rocking) motion associated with four or more CH\(_2\) groups in an open chain occurs at about 720 cm\(^{-1}\) (called a long-chain band).

C–C Stretch not interpretatively useful; many weak peaks.

Examples: decane (Fig. 2.7), mineral oil (Fig. 2.8), and cyclohexane (Fig. 2.9).
2.10 Hydrocarbons: Alkanes, Alkenes, and Alkynes

B. Alkenes

Alkenes show many more peaks than alkanes. The principal peaks of diagnostic value are the C–H stretching peaks for the \( sp^2 \) carbon at values greater than 3000 cm\(^{-1} \), along with C–H peaks for the \( sp^3 \) carbon atoms appearing below that value. Also prominent are the out-of-plane bending peaks that appear in the range 1000–650 cm\(^{-1} \). For unsymmetrical compounds, you should expect to see the C=C stretching peak near 1650 cm\(^{-1} \).

**FIGURE 2.9** The infrared spectrum of cyclohexane (neat liquid, KBr plates).

### SPECTRAL ANALYSIS BOX

**ALKENES**

- C–H: Stretch for \( sp^2 \) C–H occurs at values greater than 3000 cm\(^{-1} \) (3095–3010 cm\(^{-1} \)).
- C–H: Out-of-plane (oop) bending occurs in the range 1000–650 cm\(^{-1} \).

These bands can be used to determine the degree of substitution on the double bond (see discussion).

C=C: Stretch occurs at 1660–1600 cm\(^{-1} \); conjugation moves C=C stretch to lower frequencies and increases the intensity.

Symmetrically substituted bonds (e.g., 2,3-dimethyl-2-butene) do not absorb in the infrared (no dipole change).

Symmetrically disubstituted (trans) double bonds are often vanishingly weak in absorption; cis are stronger.

**Examples:** 1-hexene (Fig. 2.10), cyclohexene (Fig. 2.11), cis-2-pentene (Fig. 2.12), and trans-2-pentene (Fig. 2.13).
**FIGURE 2.10** The infrared spectrum of 1-hexene (neat liquid, KBr plates).

**FIGURE 2.11** The infrared spectrum of cyclohexene (neat liquid, KBr plates).

**FIGURE 2.12** The infrared spectrum of *cis*-2-pentene (neat liquid, KBr plates).
2.10 Hydrocarbons: Alkanes, Alkenes, and Alkynes

C. Alkynes

Terminal alkynes will show a prominent peak at about 3300 cm\(^{-1}\) for the \(sp\)-hybridized C–H. A C≡C will also be a prominent feature in the spectrum for the terminal alkyne, appearing at about 2150 cm\(^{-1}\). The alkyl chain will show C–H stretching frequencies for the \(sp^3\) carbon atoms. Other features include the bending bands for CH\(_2\) and CH\(_3\) groups. Nonterminal alkynes will not show the C–H band at 3300 cm\(^{-1}\). The C≡C at 2150 cm\(^{-1}\) will be very weak or absent from the spectrum.

**Spectral Analysis Box**

**Alkynes**

\(\equiv\text{C–H}\) Stretch for \(sp\) C–H usually occurs near 3300 cm\(^{-1}\).
\(\equiv\text{C}\) Stretch occurs near 2150 cm\(^{-1}\); conjugation moves stretch to lower frequency. Disubstituted or symmetrically substituted triple bonds give either no absorption or weak absorption.

**Examples:** 1-octyne (Fig. 2.14) and 4-octyne (Fig. 2.15).

![Figure 2.13](image_url) The infrared spectrum of trans-2-pentene (neat liquid, KBr plates).

![Figure 2.14](image_url) The infrared spectrum of 1-octyne (neat liquid, KBr plates).
DISCUSSION SECTION

C–H Stretch Region

The C–H stretching and bending regions are two of the most difficult regions to interpret in infrared spectra. The C–H stretching region, which ranges from 3300 to 2750 cm\(^{-1}\), is generally the more useful of the two. As discussed in Section 2.4, the frequency of the absorption of C–H bonds is a function mostly of the type of hybridization that is attributed to the bond. The \(sp^3\)-1s C–H bond present in acetylenic compounds is stronger than the \(sp^2\)-1s bond present in C=C double-bond compounds (vinyl compounds). This strength results in a larger vibrational force constant and a higher frequency of vibration. Likewise, the \(sp^2\)-1s C–H absorption in vinyl compounds occurs at a higher frequency than the \(sp^3\)-1s C–H absorption in saturated aliphatic compounds. Table 2.5 gives some physical constants for various C–H bonds involving \(sp^2\), \(sp^3\), and \(sp^3\)-hybridized carbon.

As Table 2.5 demonstrates, the frequency at which the C–H absorption occurs indicates the type of carbon to which the hydrogen is attached. Figure 2.16 shows the entire C–H stretching region. Except for the aldehyde hydrogen, an absorption frequency of less than 3000 cm\(^{-1}\) usually implies a saturated compound (only \(sp^3\)-1s hydrogens). An absorption frequency higher than 3000 cm\(^{-1}\) but not above about 3150 cm\(^{-1}\) usually implies aromatic or vinyl hydrogens. However, cyclopropyl C–H bonds, which have extra s character because of the need to put more p character into the ring C–C bonds to reduce angle distortion, also give rise to absorption in the region of 3100 cm\(^{-1}\). Cyclopropyl hydrogens can easily be distinguished from aromatic hydrogens or vinyl hydrogens by cross-reference to the C=C and C–H out-of-plane regions. The aldehyde C–H stretch appears at lower frequencies than the saturated C–H absorptions and normally consists of two weak

absorptions at about 2850 and 2750 cm$^{-1}$. The 2850-cm$^{-1}$ band usually appears as a shoulder on the saturated C–H absorption bands. The band at 2750 cm$^{-1}$ is rather weak and may be missed in an examination of the spectrum. However, it appears at lower frequencies than aliphatic $sp^3$ C–H bands. If you are attempting to identify an aldehyde, look for this pair of weak but very diagnostic bands for the aldehyde C–H stretch.

Table 2.6 lists the $sp^3$-hybridized C–H stretching vibrations for methyl, methylene, and methine. The tertiary C–H (methine hydrogen) gives only one weak C–H stretch absorption, usually near 2890 cm$^{-1}$. Methylene hydrogens (–CH$_2$–), however, give rise to two C–H stretching bands, representing the symmetric (sym) and asymmetric (asym) stretching modes of the group. In effect, the 2890-cm$^{-1}$ methine absorption is split into two bands at 2926 cm$^{-1}$ (asym) and 2853 cm$^{-1}$ (sym). The asymmetric mode generates a larger dipole moment and is of greater intensity than the symmetric mode. The splitting of the 2890-cm$^{-1}$ methine absorption is larger in the case of a methyl group. Peaks appear at about 2962 and 2872 cm$^{-1}$. Section 2.3 showed the asymmetric and symmetric stretching modes for methylene and methyl.

Since several bands may appear in the C–H stretch region, it is probably a good idea to decide only whether the absorptions are acetylenic (3300 cm$^{-1}$), vinylic or aromatic (>3000 cm$^{-1}$), aliphatic (<3000 cm$^{-1}$), or aldehydic (2850 and 2750 cm$^{-1}$). Further interpretation of C–H stretching vibrations may not be worth extended effort. The C–H bending vibrations are often more useful for determining whether methyl or methylene groups are present in a molecule.

C–H Bending Vibrations for Methyl and Methylene

The presence of methyl and methylene groups, when not obscured by other absorptions, may be determined by analyzing the region from 1465 to 1370 cm$^{-1}$. As shown in Figure 2.17, the band due to CH$\text{2}$ scissoring usually occurs at 1465 cm$^{-1}$. One of the bending modes for CH$_3$ usually absorbs strongly near 1375 cm$^{-1}$. These two bands can often be used to detect methylene and methyl groups, respectively. Furthermore, the 1375-cm$^{-1}$ methyl band is usually split into two peaks of nearly equal intensity (symmetric and asymmetric modes) if a geminal dimethyl group is present. This doublet is often observed in compounds with isopropyl groups. A tert-butyl group results in an even wider splitting of the 1375-cm$^{-1}$ band into two peaks. The 1370-cm$^{-1}$ band is more intense than the 1390-cm$^{-1}$ one. Figure 2.18 shows the expected patterns for the isopropyl and tert-butyl groups. Note that some variation from these idealized patterns may occur. Nuclear magnetic resonance spectroscopy may be used to confirm the presence of these groups. In cyclic hydrocarbons, which do not have attached methyl groups, the 1375-cm$^{-1}$ band is missing, as can be seen in the spectrum of cyclohexane (Fig. 2.9). Finally, a rocking band (Section 2.3) appears near 720 cm$^{-1}$ for long-chain alkanes of four carbons or more (see Fig. 2.7).

C=C Stretching Vibrations

Simple Alkyl-Substituted Alkenes. The C=C stretching frequency usually appears between 1670 and 1640 cm$^{-1}$ for simple noncyclic (acyclic) alkenes. The C=C frequencies increase as alkyl groups are added to a double bond. For example, simple monosubstituted alkenes yield values near 1640 cm$^{-1}$, 1,1-disubstituted alkenes absorb at about 1650 cm$^{-1}$, and tri- and tetrasubstituted alkenes absorb near 1670 cm$^{-1}$. Trans-Disubstituted alkenes absorb at higher frequencies (1670 cm$^{-1}$)

![Diagram](image-url)
than cis-disubstituted alkenes (1658 cm\(^{-1}\)). Unfortunately, the C=C group has a rather weak intensity, certainly much weaker than a typical C=O group. In many cases, such as in tetrasubstituted alkenes, the double bond absorption may be so weak that it is not observed at all. Recall from Section 2.1 that if the attached groups are arranged symmetrically, no change in dipole moment occurs during stretching, and hence no infrared absorption is observed. Cis-Alkenes, which have less symmetry than trans-alkenes, generally absorb more strongly than the latter. Double bonds in rings, because they are often symmetric or nearly so, absorb more weakly than those not contained in rings. Terminal double bonds in monosubstituted alkenes generally have stronger absorption.

**Conjugation Effects.** Conjugation of a C=C double bond with either a carbonyl group or another double bond provides the multiple bond with more single-bond character (through resonance, as the following example shows), a lower force constant \( K \), and thus a lower frequency of vibration. For example, the vinyl double bond in styrene gives an absorption at 1630 cm\(^{-1}\).

\[
\begin{align*}
\text{C} & \equiv \text{C} \quad \text{C} \equiv \text{C} \\
\text{C} & \equiv \text{C} \\
\text{C} & \equiv \text{C}
\end{align*}
\]

With several double bonds, the number of C=C absorptions often corresponds to the number of conjugated double bonds. An example of this correspondence is found in 1,3-pentadiene, where absorptions are observed at 1600 and 1650 cm\(^{-1}\). In the exception to the rule, butadiene gives only one band near 1600 cm\(^{-1}\). If the double bond is conjugated with a carbonyl group, the C=C absorption shifts to a lower frequency and is also intensified by the strong dipole of the carbonyl group. Often, two closely spaced C=C absorption peaks are observed for these conjugated systems, resulting from two possible conformations.

**Ring-Size Effects with Internal Double Bonds.** The absorption frequency of internal (endo) double bonds in cyclic compounds is very sensitive to ring size. As shown in Figure 2.19, the absorption frequency decreases as the internal angle decreases, until it reaches a minimum at 90° in cyclobutene. The frequency increases again for cyclopentene when the angle drops to 60°. This initially unexpected increase in frequency occurs because the C=C vibration in cyclopentene is strongly coupled to the attached C=C single-bond vibration. When the attached C=C bonds are perpendicular to the C=C axis, as in cyclobutene, their vibrational mode is orthogonal to that of the C=C bond (i.e., on a different axis) and does not couple. When the angle is greater than 90° (120° in the following example), the C=C single-bond stretching vibration can be resolved into two components, one of which is coincident with the direction of the C=C stretch. In the diagram, components a and b of the C=C stretching vector are shown. Since component a is in line with the C=C stretching vector, the C=C and C=C bonds are coupled, leading to a higher frequency of absorption. A similar pattern exists for cyclopropene, which has an angle less than 90°.
Infrared Spectroscopy

Significant increases in the frequency of the absorption of a double bond contained in a ring are observed when one or two alkyl groups are attached directly to the double bond. The increases are most dramatic for small rings, especially cyclopropenes. For example, Figure 2.20 shows that the base value of 1656 cm\(^{-1}\) for cyclopropene increases to about 1788 cm\(^{-1}\) when one alkyl group is attached to the double bond; with two alkyl groups the value increases to about 1883 cm\(^{-1}\).

2.10 Hydrocarbons: Alkanes, Alkenes, and Alkynes

The figure shows additional examples. It is important to realize that the ring size must be determined before the illustrated rules are applied. Notice, for example, that the double bonds in the 1,2-dialkylcyclopentene and 1,2-dialkylcyclohexene absorb at nearly the same value.

**Ring-Size Effects with External Double Bonds.** External (exo) double bonds give an increase in absorption frequency with decreasing ring size, as shown in Figure 2.21. Allene is included in the figure because it is an extreme example of an exo double-bond absorption. Smaller rings require the use of more $p$ character to make the C–C bonds form the requisite small angles (recall the trend: $sp = 180^\circ$, $sp^2 = 120^\circ$, $sp^3 = 109.5^\circ$, $sp^{>3} = <109^\circ$). This removes $p$ character from the sigma bond of the double bond but gives it more $s$ character, thus strengthening and stiffening the double bond. The force constant $K$ is then increased, and the absorption frequency increases.

**C–H Bending Vibrations for Alkenes**

The C–H bonds in alkenes can vibrate by bending both in plane and out of plane when they absorb infrared radiation. The scissoring in-plane vibration for terminal alkenes occurs at about 1415 cm$^{-1}$. This band appears at this value as a medium-to-weak absorption for both monosubstituted and 1,1-disubstituted alkenes.

The most valuable information for alkenes is obtained from analysis of the C–H out-of-plane region of the spectrum, which extends from 1000 to 650 cm$^{-1}$. These bands are frequently the strongest peaks in the spectrum. The number of absorptions and their positions in the spectrum can be used to indicate the substitution pattern on the double bond.
**Monosubstituted Double Bonds (Vinyl).** This substitution pattern gives rise to two strong bands, one near 990 cm\(^{-1}\) and the other near 910 cm\(^{-1}\) for alkyl-substituted alkenes. An overtone of the 910-cm\(^{-1}\) band usually appears at 1820 cm\(^{-1}\) and helps confirm the presence of the vinyl group. The 910-cm\(^{-1}\) band is shifted to a lower frequency, as low as 810 cm\(^{-1}\), when a group attached to the double bond can release electrons by a resonance effect (Cl, F, OR). The 910-cm\(^{-1}\) group shifts to a higher frequency, as high as 960 cm\(^{-1}\), when the group withdraws electrons by a resonance effect (C=O, C≡N). The use of the out-of-plane vibrations to confirm the monosubstituted structure is considered very reliable. The absence of these bands almost certainly indicates that this structural feature is not present within the molecule.

**cis- and trans-1,2-Disubstituted Double Bonds.** A cis arrangement about a double bond gives one strong band near 700 cm\(^{-1}\), while a trans double bond absorbs near 970 cm\(^{-1}\). This kind of information can be valuable in the assignment of stereochemistry about the double bond (see Figs. 2.12 and 2.13).

**1,1-Disubstituted Double Bonds.** One strong band near 890 cm\(^{-1}\) is obtained for a gem-dialkyl-substituted double bond. When electron-releasing or electron-withdrawing groups are attached to the double bond, shifts similar to that just given for monosubstituted double bonds are observed.

**Trisubstituted Double Bonds.** One medium-intensity band near 815 cm\(^{-1}\) is obtained.

**Tetrasubstituted Double Bonds.** These alkenes do not give any absorption in this region because of the absence of a hydrogen atom on the double bond. In addition, the C=C stretching vibration is very weak (or absent) at about 1670 cm\(^{-1}\) in these highly substituted systems.

Figure 2.22 shows the C—H out-of-plane bending vibrations for substituted alkenes, together with the frequency ranges.

**FIGURE 2.22** The C—H out-of-plane bending vibrations for substituted alkenes.
2.11 Aromatic Rings

Aromatic compounds show a number of absorption bands in the infrared spectrum, many of which are not of diagnostic value. The C–H stretching peaks for the sp² carbon appear at values greater than 3000 cm⁻¹. Since C–H stretching bands for alkenes appear in the same range, it may be difficult to use the C–H stretching bands to differentiate between alkenes and aromatic compounds. However, the C=C stretching bands for aromatic rings usually appear between 1600 and 1450 cm⁻¹ outside the usual range where the C=C appears for alkenes (1650 cm⁻¹). Also prominent are the out-of-plane bending peaks that appear in the range 900–690 cm⁻¹, which, along with weak overtone bands at 2000–1667 cm⁻¹, can be used to assign substitution on the ring.

SPECTRAL ANALYSIS BOX

AROMATIC RINGS

= C–H     Stretch for sp² C–H occurs at values greater than 3000 cm⁻¹ (3050–3010 cm⁻¹).

= C–H     Out-of-plane (oop) bending occurs at 900–690 cm⁻¹. These bands can be used with great utility to assign the ring substitution pattern (see discussion).

C=C       Ring stretch absorptions often occur in pairs at 1600 cm⁻¹ and 1475 cm⁻¹.

Overtone/combination bands appear between 2000 and 1667 cm⁻¹. These weak absorptions can be used to assign the ring substitution pattern (see discussion).

Examples: toluene (Fig. 2.23), ortho-diethylbenzene (Fig. 2.24), meta-diethylbenzene (Fig. 2.25), para-diethylbenzene (Fig. 2.26), and styrene (Fig. 2.27).

**FIGURE 2.26** The infrared spectrum of para-diethylbenzene (neat liquid, KBr plates).
DISCUSSION SECTION

C–H Bending Vibrations

The in-plane C–H bending vibrations occur between 1300 and 1000 cm\(^{-1}\). However, these bands are rarely useful because they overlap other, stronger absorptions that occur in this region.

The out-of-plane C–H bending vibrations, which appear between 900 and 690 cm\(^{-1}\), are far more useful than the in-plane bands. These extremely intense absorptions, resulting from strong coupling with adjacent hydrogen atoms, can be used to assign the positions of substituents on the aromatic ring. The assignment of structure based on these out-of-plane bending vibrations is most reliable for alkyl-, alkoxy-, halo-, amino-, or carbonyl-substituted aromatic compounds. Aromatic nitro compounds, derivatives of aromatic carboxylic acids, and derivatives of sulfonic acids sometimes lead to unsatisfactory interpretation.

Monosubstituted Rings. This substitution pattern always gives a strong absorption near 690 cm\(^{-1}\). If this band is absent, no monosubstituted ring is present. A second strong band usually appears near 750 cm\(^{-1}\). When the spectrum is taken in a halocarbon solvent, the 690-cm\(^{-1}\) band may be obscured by the strong C–X stretch absorptions. The typical two-peak monosubstitution pattern appears in the spectra of toluene (Fig. 2.23) and styrene (Fig. 2.27). In addition, the spectrum of styrene shows a pair of bands for the vinyl out-of-plane bending modes.

ortho-Disubstituted Rings (1,2-Disubstituted Rings). One strong band near 750 cm\(^{-1}\) is obtained. This pattern is seen in the spectrum of ortho-diethylbenzene (Fig. 2.24).

meta-Disubstituted Rings (1,3-Disubstituted Rings). This substitution pattern gives the 690-cm\(^{-1}\) band plus one near 780 cm\(^{-1}\). A third band of medium intensity is often found near 880 cm\(^{-1}\). This pattern is seen in the spectrum of meta-diethylbenzene (Fig. 2.25).
para-Disubstituted Rings (1,4-Disubstituted Rings). One strong band appears in the region from 800 to 850 cm\(^{-1}\). This pattern is seen in the spectrum of para-diethylbenzene (Fig. 2.26).

Figure 2.28a shows the C–H out-of-plane bending vibrations for the common substitution patterns already given plus some others, together with the frequency ranges. Note that the bands appearing in the 720- to 667-cm\(^{-1}\) region (shaded boxes) actually result from C=C out-of-plane ring bending vibrations rather than from C–H out-of-plane bending.

Combinations and Overtone Bands

Many weak combination and overtone absorptions appear between 2000 and 1667 cm\(^{-1}\). The relative shapes and number of these peaks can be used to tell whether an aromatic ring is mono-, di-, tri-, tetra-, penta-, or hexa-substituted. Positional isomers can also be distinguished. Since the absorptions are weak, these bands are best observed by using neat liquids or concentrated solutions. If the compound has a high-frequency carbonyl group, this absorption will overlap the weak overtone bands so that no useful information can be obtained from the analysis of the region.

Figure 2.28b shows the various patterns obtained in this region. The monosubstitution pattern that appears in the spectra of toluene (Fig. 2.23) and styrene (Fig. 2.27) is particularly useful and

helps to confirm the out-of-plane data given in the preceding section. Likewise, the ortho-, meta-, and para-disubstituted patterns may be consistent with the out-of-plane bending vibrations discussed earlier. The spectra of ortho-diethylbenzene (Fig. 2.24), meta-diethylbenzene (Fig. 2.25), and para-diethylbenzene (Fig. 2.26) each show bands in both the 2000- to 1667-cm\(^{-1}\) and 900- to 690-cm\(^{-1}\) regions, consistent with their structures. Note, however, that the out-of-plane vibrations are generally more useful for diagnostic purposes.

### 2.12 ALCOHOLS AND PHENOLS

Alcohols and phenols will show strong and broad hydrogen-bonded O–H stretching bands centered between 3400 and 3300 cm\(^{-1}\). In solution, it will also be possible to observe a “free” O–H (non-H–bonded) stretching band at about 3600 cm\(^{-1}\) (sharp and weaker) to the left of the hydrogen-bonded O–H peak. In addition, a C–O stretching band will appear in the spectrum at 1260–1000 cm\(^{-1}\).

#### SPECTRAL ANALYSIS BOX

**ALCOHOLS AND PHENOLS**

O–H

The free O–H stretch is a sharp peak at 3650–3600 cm\(^{-1}\). This band appears in combination with the hydrogen-bonded O–H peak when the alcohol is dissolved in a solvent (see discussion).

The hydrogen-bonded O–H band is a broad peak at 3400–3300 cm\(^{-1}\). This band is usually the only one present in an alcohol that has not been dissolved in a solvent (neat liquid). When the alcohol is dissolved in a solvent, the free O–H and hydrogen-bonded O–H bands are present together, with the relatively weak free O–H on the left (see discussion).

C–O–H

Bending appears as a broad and weak peak at 1440–1220 cm\(^{-1}\), often obscured by the CH\(_3\) bendings.

C–O

Stretching vibration usually occurs in the range 1260–1000 cm\(^{-1}\). This band can be used to assign a primary, secondary, or tertiary structure to an alcohol (see discussion).

**Examples:** The hydrogen-bonded O–H stretch is present in the pure liquid (neat) samples of 1-hexanol (Fig. 2.29), 2-butanol (Fig. 2.30), and para-cresol (Fig. 2.31).

---

**FIGURE 2.29** The infrared spectrum of 1-hexanol (neat liquid, KBr plates).
**DISCUSSION SECTION**

**O−H Stretching Vibrations**

When alcohols or phenols are determined as pure (neat) liquid films, as is common practice, a broad O−H stretching vibration is obtained for intermolecular hydrogen bonding in the range from 3400 to 3300 cm⁻¹. Figure 2.32a shows this band, which is observed in the spectra of 1-hexanol (Fig. 2.29) and 2-butanol (Fig. 2.30). Phenols also show the hydrogen-bonded O−H (Fig. 2.31). As the alcohol is diluted with carbon tetrachloride, a sharp “free” (non-hydrogen-bonded) O−H stretching band appears at about 3600 cm⁻¹, to the left of the broad band (Fig. 2.32b). When the solution is further diluted, the broad intermolecular hydrogen-bonded band is reduced considerably, leaving as the major band the free O−H stretching absorption (Fig. 2.32c). Intermolecular hydrogen bonding weakens the O−H bond, thereby shifting the band to lower frequency (lower energy).

Some workers have used the position of the free O−H stretching band to help assign a primary, secondary, or tertiary structure to an alcohol. For example, the free stretch occurs near 3640, 3630, 3620, and 3610 cm⁻¹ for primary, secondary, and tertiary alcohols and for phenols, respectively. These absorptions can be analyzed only if the O−H region is expanded and carefully calibrated. Under the usual routine laboratory conditions, these fine distinctions are of little use. Far more useful information is obtained from the C−O stretching vibrations.
Intramolecular hydrogen bonding, present in ortho-carbonyl-substituted phenols, usually shifts the broad O–H band to a lower frequency. For example, the O–H band is centered at about 3200 cm$^{-1}$ in the neat spectrum of methyl salicylate, while O–H bands from normal phenols are centered at about 3350 cm$^{-1}$. The intramolecular hydrogen-bonded band does not change its position significantly even at high dilution because the internal bonding is not altered by a change in concentration.

Although phenols often have broader O–H bands than alcohols, it is difficult to assign a structure based on this absorption; use the aromatic C=C region and the C–O stretching vibration (to be discussed shortly) to assign a phenolic structure. Finally, the O–H stretching vibrations in carboxylic acids also occur in this region. They may easily be distinguished from alcohols and phenols by the presence of a very broad band extending from 3400 to 2400 cm$^{-1}$ and the presence of a carbonyl absorption (see Section 2.14D).

**C–O–H Bending Vibrations**

This bending vibration is coupled to H–C–H bending vibrations to yield some weak and broad peaks in the 1440 to 1220-cm$^{-1}$ region. These broad peaks are difficult to observe because they are usually located under the more strongly absorbing CH$_3$ bending peaks at 1375 cm$^{-1}$ (see Fig. 2.29).

**C–O Stretching Vibrations**

The strong C–O single-bond stretching vibrations are observed in the range from 1260 to 1000 cm$^{-1}$. Since the C–O absorptions are coupled with the adjacent C–C stretching vibrations, the position of the band may be used to assign a primary, secondary, or tertiary structure to an alcohol or to determine whether a phenolic compound is present. Table 2.7 gives the expected absorption bands for the C–O stretching vibrations in alcohols and phenols. For comparison, the O–H stretch values are also tabulated.
2.13 ETHERS

Ethers show at least one C–O band in the range 1300–1000 cm\(^{-1}\). Simple aliphatic ethers can be distinguished from alkanes by the presence of the C–O band. In all other respects, the spectra of simple ethers look very similar to those of alkanes. Aromatic ethers, epoxides, and acetals are discussed in this section.
ETHERS

The most prominent band is that due to C–O stretch, 1300–1000 cm\(^{-1}\). Absence of C=O and O–H is required to ensure that C–O stretch is not due to an ester or an alcohol. Phenyl alkyl ethers give two strong bands at about 1250 and 1040 cm\(^{-1}\), while aliphatic ethers give one strong band at about 1120 cm\(^{-1}\).

Examples: dibutyl ether (Fig. 2.33) and anisole (Fig. 2.34).

FIGURE 2.33 The infrared spectrum of dibutyl ether (neat liquid, KBr plates).

FIGURE 2.34 The infrared spectrum of anisole (neat liquid, KBr plates).

DISCUSSION SECTION

Ethers and related compounds such as epoxides, acetals, and ketals give rise to C–O–C stretching absorptions in the range from 1300 to 1000 cm\(^{-1}\). Alcohols and esters also give strong C–O absorptions in this region, and these latter possibilities must be eliminated by observing the absence of bands in the O–H stretch region (Section 2.12) and in the C=O stretch region (Section 2.14), respectively. Ethers are generally encountered more often than epoxides, acetals, and ketals.
52 Infrared Spectroscopy

Dialkyl Ethers. The asymmetric C–O–C stretching vibration leads to a single strong absorption that appears at about 1120 cm\(^{-1}\), as seen in the spectrum of dibutyl ether (Fig. 2.33). The symmetric stretching band at about 850 cm\(^{-1}\) is usually very weak. The asymmetric C–O–C absorption also occurs at about 1120 cm\(^{-1}\) for a six-membered ring containing oxygen.

Aryl and Vinyl Ethers. Aryl alkyl ethers give rise to two strong bands: an asymmetric C–O–C stretch near 1250 cm\(^{-1}\) and a symmetric stretch near 1040 cm\(^{-1}\), as seen in the spectrum of anisole (Fig. 2.34). Vinyl alkyl ethers also give two bands: one strong band assigned to an asymmetric stretching vibration at about 1220 cm\(^{-1}\) and one very weak band due to a symmetric stretch at about 850 cm\(^{-1}\).

The shift in the asymmetric stretching frequencies in aryl and vinyl ethers to values higher than were found in dialkyl ethers can be explained through resonance. For example, the C–O band in vinyl alkyl ethers is shifted to a higher frequency (1220 cm\(^{-1}\)) because of the increased double-bond character, which strengthens the bond. In dialkyl ethers the absorption occurs at 1120 cm\(^{-1}\). In addition, because resonance increases the polar character of the C–C double bond, the band at about 1640 cm\(^{-1}\) is considerably stronger than in normal C–C absorption (Section 2.10B).

Epoxides. These small-ring compounds give a weak ring-stretching band (breathing mode) in the range 1280–1230 cm\(^{-1}\). Of more importance are the two strong ring deformation bands, one that appears between 950 and 815 cm\(^{-1}\) (asymmetric) and the other between 880 and 750 cm\(^{-1}\) (symmetric). For monosubstituted epoxides, this latter band appears in the upper end of the range, often near 835 cm\(^{-1}\). Disubstituted epoxides have absorption in the lower end of the range, closer to 775 cm\(^{-1}\).

Acetals and Ketals. Molecules that contain ketal or acetal linkages often give four or five strong bands, respectively, in the region from 1200 to 1020 cm\(^{-1}\). These bands are often unresolved.

2.14 CARBONYL COMPOUNDS

The carbonyl group is present in aldehydes, ketones, acids, esters, amides, acid chlorides, and anhydrides. This group absorbs strongly in the range from 1850 to 1650 cm\(^{-1}\) because of its large change in dipole moment. Since the C=O stretching frequency is sensitive to attached atoms, the common functional groups already mentioned absorb at characteristic values. Figure 2.35 provides the normal base values for the C=O stretching vibrations of the various functional groups. The C=O frequency of a ketone, which is approximately in the middle of the range, is usually considered the reference point for comparisons of these values.
The range of values given in Figure 2.35 may be explained through the use of electron-withdrawing effects (inductive effects), resonance effects, and hydrogen bonding. The first two effects operate in opposite ways to influence the C=O stretching frequency. First, an electronegative element may tend to draw in the electrons between the carbon and oxygen atoms through its electron-withdrawing effect, so that the C=O bond becomes somewhat stronger. A higher-frequency (higher-energy) absorption results. Since oxygen is more electronegative than carbon, this effect dominates in an ester to raise the C=O frequency above that of a ketone. Second, a resonance effect may be observed when the unpaired electrons on a nitrogen atom conjugate with the carbonyl group, resulting in increased single-bond character and a lowering of the C=O absorption frequency. This second effect is observed in an amide. Since nitrogen is less electronegative than an oxygen atom, it can more easily accommodate a positive charge. The resonance structure shown here introduces single-bond character into the C=O group and thereby lowers the absorption frequency below that of a ketone.

Ester

![Ester resonance structure]

Amide

![Amide resonance structure]

Electron-withdrawing effect raises C=O frequency

Resonance effect lowers C=O frequency

In acid chlorides, the highly electronegative halogen atom strengthens the C=O bond through an enhanced inductive effect and shifts the frequency to values even higher than are found in esters. Anhydrides are likewise shifted to frequencies higher than are found in esters because of a concentration of electronegative oxygen atoms. In addition, anhydrides give two absorption bands that are due to symmetric and asymmetric stretching vibrations (Section 2.3).

A carboxylic acid exists in monomeric form only in very dilute solution, and it absorbs at about 1760 cm\(^{-1}\) because of the electron-withdrawing effect just discussed. However, acids in concentrated solution, in the form of neat liquid, or in the solid state (KBr pellet and Nujol) tend to dimerize via hydrogen bonding. This dimerization weakens the C=O bond and lowers the stretching force constant \(K\), resulting in a lowering of the carbonyl frequency of saturated acids to about 1710 cm\(^{-1}\).
Ketones absorb at a lower frequency than aldehydes because of their additional alkyl group, which is electron donating (compared to H) and supplies electrons to the C=O bond. This electron-releasing effect weakens the C=O bond in the ketone and lowers the force constant and the absorption frequency.

\]

**A. Factors that Influence the C=O Stretching Vibration**

**Conjugation Effects.** The introduction of a C=C bond adjacent to a carbonyl group results in delocalization of the \( \pi \) electrons in the C=O and C=C bonds. This conjugation increases the single-bond character of the C=O and C=C bonds in the resonance hybrid and hence lowers their force constants, resulting in a lowering of the frequencies of carbonyl and double-bond absorption. Conjugation with triple bonds also shows this effect.

\text{O} & \quad \text{C} & \quad \text{O} \\
\text{C} & \quad \text{C} & \quad \text{C} \\
\end{align*}
\]

Generally, the introduction of an \( \alpha,\beta \) double bond in a carbonyl compound results in a 25- to 45-cm\(^{-1}\) lowering of the C=O frequency from the base value given in Figure 2.35. A similar lowering occurs when an adjacent aryl group is introduced. Further addition of unsaturation (\( \chi,\delta \)) results in a further shift to lower frequency, but only by about 15 cm\(^{-1}\) more. In addition, the C=C absorption shifts from its “normal” value, about 1650 cm\(^{-1}\), to a lower-frequency value of about 1640 cm\(^{-1}\), and the C=C absorption is greatly intensified. Often, two closely spaced C=O absorption peaks are observed for these conjugated systems, resulting from two possible conformations, the \textit{s-cis} and \textit{s-trans}. The \textit{s-cis} conformation absorbs at a frequency higher than the \textit{s-trans} conformation. In some cases, the C=O absorption is broadened rather than split into the doublet.

\[
\begin{align*}
\text{C=C} & \quad \text{R} \\
\text{C=O} & \quad \text{R} \\
\text{s-cis} & \quad \text{s-trans} \\
\end{align*}
\]

The following examples show the effects of conjugation on the C=O frequency.

\[
\begin{align*}
1715 & \quad 1690 \text{ cm}^{-1} \\
1725 & \quad 1700 \text{ cm}^{-1} \\
1710 & \quad 1680 \text{ cm}^{-1} \\
\end{align*}
\]

\( \alpha,\beta \)-Unsaturated ketone
Aryl-substituted aldehyde
Aryl-substituted acid

Conjugation does not reduce the C=O frequency in amides. The introduction of \( \alpha,\beta \) unsaturation causes an \textit{increase in frequency} from the base value given in Figure 2.35. Apparently, the
introduction of \(sp^2\)-hybridized carbon atoms removes electron density from the carbonyl group and strengthens the bond instead of interacting by resonance as in other carbonyl examples. Since the parent amide group is already highly stabilized (see p. 53), the introduction of the C=C unsaturation does not overcome this resonance.

**Ring-Size Effects.** Six-membered rings with carbonyl groups are unstrained and absorb at about the values given in Figure 2.35. Decreasing the ring size increases the frequency of the C=O absorption for the reasons discussed in Section 2.10 (C=C stretching vibrations and exocyclic double bonds; p. 41). All of the functional groups listed in Figure 2.35, which can form rings, give increased frequencies of absorption with increased angle strain. For ketones and esters, there is often a 30-cm\(^{-1}\) increase in frequency for each carbon removed from the unstrained six-membered ring values. Some examples are

<table>
<thead>
<tr>
<th>Cyclic ketone</th>
<th>Cyclic ketone</th>

<th>Cyclic amide (lactam)</th>
</tr>
</thead>
<tbody>
<tr>
<td>(1715 \rightarrow 1745) cm(^{-1})</td>
<td>(1715 \rightarrow 1780) cm(^{-1})</td>
<td>(1735 \rightarrow 1770) cm(^{-1})</td>
<td>(1690 \rightarrow 1705) cm(^{-1})</td>
</tr>
</tbody>
</table>

In ketones, larger rings have frequencies that range from nearly the same value as in cyclohexanone (1715 cm\(^{-1}\)) to values slightly less than 1715 cm\(^{-1}\). For example, cycloheptanone absorbs at about 1705 cm\(^{-1}\).

**\(\alpha\)-Substitution Effects.** When the carbon next to the carbonyl is substituted with a chlorine (or other halogen) atom, the carbonyl band shifts to a higher frequency. The electron-withdrawing effect removes electrons from the carbon of the C=O bond. This removal is compensated for by a tightening of the \(\pi\) bond (shortening), which increases the force constant and leads to an increase in the absorption frequency. This effect holds for all carbonyl compounds.

In ketones, two bands result from the substitution of an adjacent chlorine atom. One arises from the conformation in which the chlorine is rotated next to the carbonyl, and the other is due to the conformation in which the chlorine is away from the group. When the chlorine is next to the carbonyl, nonbonded electrons on the oxygen atom are repelled, resulting in a stronger bond and a higher absorption frequency. Information of this kind can be used to establish a structure in rigid ring systems, such as in the following examples:
Hydrogen-Bonding Effects. Hydrogen bonding to a carbonyl group lengthens the C=O bond and lowers the stretching force constant \( K \), resulting in a lowering of the absorption frequency. Examples of this effect are the decrease in the C=O frequency of the carboxylic acid dimer (p. 53) and the lowering of the ester C=O frequency in methyl salicylate caused by intramolecular hydrogen bonding:

![Methyl salicylate](image)

1680 cm\(^{-1}\)

B. Aldehydes

Aldehydes show a very strong band for the carbonyl group (C=O) that appears in the range of 1740–1725 cm\(^{-1}\) for simple aliphatic aldehydes. This band is shifted to lower frequencies with conjugation to a C=C or phenyl group. A very important doublet can be observed in the C–H stretch region for the aldehyde C–H near 2850 and 2750 cm\(^{-1}\). The presence of this doublet allows aldehydes to be distinguished from other carbonyl-containing compounds.

### SPECTRAL ANALYSIS BOX

**ALDEHYDES**

\[ \text{C}=\text{O} \]

\[ \text{R} \quad \text{C} \quad \text{H} \quad \text{O} \]

C=O stretch appears in the range 1740–1725 cm\(^{-1}\) for normal aliphatic aldehydes.

\[ \text{C}=\text{C} \quad \text{C} \quad \text{H} \quad \text{O} \]

Conjugation of C=O with \( \alpha, \beta \text{C}=\text{C} \); 1700–1680 cm\(^{-1}\) for C=O and 1640 cm\(^{-1}\) for C=C.

\[ \text{Ar} \quad \text{C} \quad \text{H} \quad \text{O} \]

Conjugation of C=O with phenyl; 1700–1660 cm\(^{-1}\) for C=O and 1600–1450 cm\(^{-1}\) for ring.

\[ \text{Ar} \quad \text{C}=\text{C} \quad \text{C} \quad \text{H} \quad \text{O} \]

Longer conjugated system; 1680 cm\(^{-1}\) for C=O.

\[ \text{C}=\text{H} \]

Stretch, aldehyde hydrogen (–CHO), consists of a pair of weak bands, one at 2860–2800 cm\(^{-1}\) and the other at 2760–2700 cm\(^{-1}\). It is easier to see the band at the lower frequency because it is not obscured by the usual C–H bands from the alkyl chain. The higher-frequency aldehyde C–H stretch is often buried in the aliphatic C–H bands.

**Examples:** nonanal (Fig. 2.36), crotonaldehyde (Fig. 2.37), and benzaldehyde (Fig. 2.38).
**FIGURE 2.36** The infrared spectrum of nonanal (neat liquid, KBr plates).

**FIGURE 2.37** The infrared spectrum of crotonaldehyde (neat liquid, KBr plates).

**FIGURE 2.38** The infrared spectrum of benzaldehyde (neat liquid, KBr plates).
DISCUSSION SECTION

The spectrum of nonanal (Fig. 2.36) exhibits the normal aldehyde stretching frequency at 1725 cm\(^{-1}\). Since the positions of these absorptions are not very different from those of ketones, it may not be easy to distinguish between aldehydes and ketones on this basis. Conjugation of the carbonyl group with an aryl or an \(\alpha,\beta\) double bond shifts the normal C=O stretching band to a lower frequency (1700–1680 cm\(^{-1}\)), as predicted in Section 2.14A (Conjugation Effects). This effect is seen in crotonaldehyde (Fig. 2.37), which has \(\alpha,\beta\) unsaturation, and in benzaldehyde (Fig. 2.38), in which an aryl group is attached directly to the carbonyl group. Halogenation on the \(\alpha\) carbon leads to an increased frequency for the carbonyl group (p. 55).

The C–H stretching vibrations found in aldehydes (–CHO) at about 2750 and 2850 cm\(^{-1}\) are extremely important for distinguishing between ketones and aldehydes. Typical ranges for the pairs of C–H bands are 2860–2800 and 2760–2700 cm\(^{-1}\). The band at 2750 cm\(^{-1}\) is probably the more useful of the pair because it appears in a region where other C–H absorptions (CH\(_3\), CH\(_2\), and so on) are absent. The 2850-cm\(^{-1}\) band often overlaps other C–H bands and is not as easy to see (see nonanal, Fig. 2.36). If the 2750-cm\(^{-1}\) band is present together with the proper C=O absorption value, an aldehyde functional group is almost certainly indicated.

The doublet that is observed in the range 2860–2700 cm\(^{-1}\) for an aldehyde is a result of Fermi resonance (p. 19). The second band appears when the aldehyde C–H stretching vibration is coupled with the first overtone of the medium-intensity aldehyde C–H bending vibration appearing in the range 1400–1350 cm\(^{-1}\).

The medium-intensity absorption in nonanal (Fig. 2.36) at 1460 cm\(^{-1}\) is due to the scissoring (bending) vibration of the CH\(_2\) group next to the carbonyl group. Methylene groups often absorb more strongly when they are attached directly to a carbonyl group.

C. Ketones

Ketones show a very strong band for the C=O group that appears in the range of 1720–1708 cm\(^{-1}\) for simple aliphatic ketones. This band is shifted to lower frequencies with conjugation to a C=C or phenyl group. An \(\alpha\)-halogen atom will shift the C=O frequency to a higher value. Ring strain moves the absorption to a higher frequency in cyclic ketones.

\]
Conjugation with two aromatic rings; 1670–1600 cm\(^{-1}\) for C=O.

Cyclic ketones; C=O frequency increases with decreasing ring size.

Bending appears as a medium-intensity peak in the range 1300–1100 cm\(^{-1}\).

**Examples:** 3-methyl-2-butanone (Fig. 2.4), mesityl oxide (Fig. 2.39), acetophenone (Fig. 2.40), cyclopentanone (Fig. 2.41), and 2,4-pentanedione (Fig. 2.42).

**Figure 2.39** The infrared spectrum of mesityl oxide (neat liquid, KBr plates).

**Figure 2.40** The infrared spectrum of acetophenone (neat liquid, KBr plates).
Discussion Section

Normal C=O Bands. The spectrum of 3-methyl-2-butanone (Fig. 2.4) exhibits a normal, or unconjugated, ketone stretching frequency at 1715 cm\(^{-1}\). A very weak overtone band from the C=O (1715 cm\(^{-1}\)) appears at twice the frequency of the C=O absorption (3430 cm\(^{-1}\)). Small bands of this type should not be confused with O–H absorptions, which also appear near this value. The O–H stretching absorptions are much more intense.

Conjugation Effects. Conjugation of the carbonyl group with an aryl or an \(\alpha,\beta\) double bond shifts the normal C=O stretching band (1715 cm\(^{-1}\)) to a lower frequency (1700 –1675 cm\(^{-1}\)), as predicted in Section 2.14A (p. 54). Rotational isomers may lead to a splitting or broadening of the carbonyl band (p. 54). The effect of conjugation on the C=O band is seen in mesityl oxide (Fig. 2.39), which has \(\alpha,\beta\) unsaturation, and in acetophenone (Fig. 2.40), in which an aryl group is attached to the carbonyl group. Both exhibit C=O shifts to lower frequencies. Figure 2.43 presents some typical C=O stretching vibrations, which demonstrate the influence of conjugation.

Cyclic Ketones (Ring Strain). Figure 2.44 provides some values for the C=O absorptions for cyclic ketones. Note that ring strain shifts the absorption values to a higher frequency, as was predicted in
Section 2.14A (p. 55). Ketene is included in Figure 2.44 because it is an extreme example of an exo double-bond absorption (see p. 41). The $s$ character in the $\text{C}=$O group increases as the ring size decreases, until it reaches a maximum value that is found in the $sp$-hybridized carbonyl carbon in ketene. The spectrum of cyclopentanone (Fig. 2.41) shows how ring strain increases the frequency of the carbonyl group.

**α-Diketones (1,2-Diketones).** Unconjugated diketones that have the two carbonyl groups adjacent to each other show one strong absorption peak at about 1716 cm$^{-1}$. If the two carbonyl groups are conjugated with aromatic rings, the absorption is shifted to a lower-frequency value, about 1680 cm$^{-1}$. In the latter case, a narrowly spaced doublet rather than a single peak may be observed due to symmetric and asymmetric absorptions.

**β-Diketones (1,3-Diketones).** Diketones with carbonyl groups located 1,3 with respect to each other may yield a more complicated pattern than those observed for most ketones (2,4-pentanedione, Fig. 2.42). These β-diketones often exhibit tautomerization, which yields an equilibrium mixture of enol and keto tautomers. Since many β-diketones contain large amounts of the enol form, you may observe carbonyl peaks for both the enol and keto tautomers.
The carbonyl group in the enol form appearing at about 1622 cm\(^{-1}\) is substantially shifted and intensified in comparison to the normal ketone value, 1715 cm\(^{-1}\). The shift is a result of internal hydrogen bonding, as discussed in Section 2.14A (p. 56). Resonance, however, also contributes to the lowering of the carbonyl frequency in the enol form. This effect introduces single-bond character into the enol form.

A weak, broad O–H stretch is observed for the enol form at 3200–2400 cm\(^{-1}\). Since the keto form is also present, a doublet for the asymmetric and symmetric stretching frequencies is observed for the two carbonyl groups (Fig. 2.42). The relative intensities of the enol and keto carbonyl absorptions depend on the percentages present at equilibrium. Hydrogen-bonded carbonyl groups in enol forms are often observed in the region 1640–1570 cm\(^{-1}\). The keto forms generally appear as doublets in the range from 1730 to 1695 cm\(^{-1}\).

\(\text{\alphahaloketones.}\) Substitution of a halogen atom on the \(\alpha\) carbon shifts the carbonyl absorption peak to a higher frequency, as discussed in Section 2.14A (p. 55). Similar shifts occur with other electron-withdrawing groups, such as an alkoxy group (–O–CH\(_3\)). For example, the carbonyl group in chloroacetone appears at 1750 cm\(^{-1}\), whereas that in methoxyacetone appears at 1731 cm\(^{-1}\). When the more electronegative fluorine atom is attached, the frequency shifts to an even higher value, 1781 cm\(^{-1}\), in fluoroacetone.

\(\text{\bendingmodes.}\) A medium-to-strong absorption occurs in the range from 1300 to 1100 cm\(^{-1}\) for coupled stretching and bending vibrations in the C–CO–C group of ketones. Aliphatic ketones absorb to the right in this range (1220 to 1100 cm\(^{-1}\)), as seen in the spectrum of 3-methyl-2-butane (Fig. 2.4), where a band appears at about 1180 cm\(^{-1}\). Aromatic ketones absorb to the left in this range (1300 to 1220 cm\(^{-1}\)), as seen in the spectrum of acetophenone (Fig. 2.40), where a band appears at about 1260 cm\(^{-1}\).

A medium-intensity band appears for a methyl group adjacent to a carbonyl at about 1370 cm\(^{-1}\) for the symmetric bending vibration. These methyl groups absorb with greater intensity than methyl groups found in hydrocarbons.

\(\text{\dcarboxylicacids.}\) Carboxylic acids show a very strong band for the C=O group that appears in the range of 1730–1700 cm\(^{-1}\) for simple aliphatic carboxylic acids in the \(\text{dimeric}\) form (p. 53). This band is shifted to lower frequencies with conjugation to a C=C or phenyl group. The O–H stretch appears in the spectrum as a very broad band extending from 3400 to 2400 cm\(^{-1}\). This broad band centers on about 3000 cm\(^{-1}\) and partially obscures the C–H stretching bands. If this very broad O–H stretch band is seen along with a C=O peak, it almost certainly indicates the compound is a carboxylic acid.
SPECTRAL ANALYSIS BOX

CARBOXYLIC ACIDS

O–H Stretch, usually very broad (strongly H-bonded), occurs at 3400–2400 cm\(^{-1}\) and often overlaps the C–H absorptions.

C=O Stretch, broad, occurs at 1730 –1700 cm\(^{-1}\). Conjugation moves the absorption to a lower frequency.

C–O Stretch occurs in the range 1320 –1210 cm\(^{-1}\), medium intensity.

Examples: isobutyric acid (Fig. 2.45) and benzoic acid (Fig. 2.46).

**Figure 2.45** The infrared spectrum of isobutyric acid (neat liquid, KBr plates).

**Figure 2.46** The infrared spectrum of benzoic acid (Nujol mull, KBr plates). Dots indicate the Nujol (mineral oil) absorption bands (see Fig. 2.8).
DISCUSSION SECTION

The most characteristic feature in the spectrum of a carboxylic acid is the extremely broad O–H absorption occurring in the region from 3400 to 2400 cm\(^{-1}\). This band is attributed to the strong hydrogen bonding present in the dimer, which was discussed in the introduction to Section 2.14 (p. 53). The absorption often obscures the C–H stretching vibrations that occur in the same region. If this broad hydrogen-bonded band is present together with the proper C=O absorption value, a carboxylic acid is almost certainly indicated. Figures 2.45 and 2.46 show the spectra of an aliphatic carboxylic acid and an aromatic carboxylic acid, respectively.

The carbonyl stretching absorption, which occurs at about 1730 to 1700 cm\(^{-1}\) for the dimer, is usually broader and more intense than that present in an aldehyde or a ketone. For most acids, when the acid is diluted with a solvent, the C=O absorption appears between 1760 and 1730 cm\(^{-1}\) for the monomer. However, the monomer is not often seen experimentally since it is usually easier to run the spectrum as a neat liquid. Under these conditions, as well as in a potassium bromide pellet or a Nujol mull, the dimer exists. It should be noted that some acids exist as dimers even at high dilution. Conjugation with a C=C or aryl group usually shifts the absorption band to a lower frequency, as predicted in Section 2.14A (p. 54) and as shown in the spectrum of benzoic acid (Fig. 2.46). Halogenation on the \(\alpha\) carbon leads to an increase in the C=O frequency. Section 2.18 discusses salts of carboxylic acids.

The C–O stretching vibration for acids (dimer) appears near 1260 cm\(^{-1}\) as a medium-intensity band. A broad band, attributed to the hydrogen-bonded O–H out-of-plane bending vibration, appears at about 930 cm\(^{-1}\). This latter band is usually of low-to-medium intensity.

E. Esters

Esters show a very strong band for the C=O group that appears in the range of 1750–1735 cm\(^{-1}\) for simple aliphatic esters. The C=O band is shifted to lower frequencies when it is conjugated to a C=C or phenyl group. On the other hand, conjugation of a C=C or phenyl group with the single-bonded oxygen of an ester leads to an increased frequency from the range given above. Ring strain moves the C=O absorption to a higher frequency in cyclic esters (lactones).

**Figure 2.50** The infrared spectrum of methyl benzoate (neat liquid, KBr plates).

**Figure 2.51** The infrared spectrum of methyl salicylate (neat liquid, KBr plates).
DISCUSSION SECTION

General Features of Esters. The two most characteristic features in the spectrum of a normal ester are the strong C=O, which appears in the range from 1750 to 1735 cm\(^{-1}\), and C–O stretching absorptions, which appear in the range from 1300 to 1000 cm\(^{-1}\). Although some ester carbonyl groups may appear in the same general area as ketones, one can usually eliminate ketones from consideration by observing the strong and broad C–O stretching vibrations that appear in a region (1300 to 1000 cm\(^{-1}\)) where ketonic absorptions appear as weaker and narrower bands. For example, compare the spectrum of a ketone, mesityl oxide (Fig. 2.39) with that of an ester, ethyl butyrate (Fig. 2.47) in the 1300- to 1000-cm\(^{-1}\) region. Ethyl butyrate (Fig. 2.47) shows the typical C=O stretching vibration at about 1738 cm\(^{-1}\).

Conjugation with a Carbonyl Group (\(\alpha,\beta\) Unsaturation or Aryl Substitution). The C=O stretching vibrations are shifted by about 15 to 25 cm\(^{-1}\) to lower frequencies with \(\alpha,\beta\) unsaturation or aryl substitution, as predicted in Section 2.14A (Conjugation Effects, p. 54). The spectra of both methyl methacrylate (Fig. 2.48) and methyl benzoate (Fig. 2.50) show the C=O absorption shift from the position in a normal ester, ethyl butyrate (Fig. 2.47). Also notice that the C=C absorption band at 1630 cm\(^{-1}\) in methyl methacrylate has been intensified over what is obtained with a nonconjugated double bond (Section 2.10B).

Conjugation with the Ester Single-Bonded Oxygen. Conjugation involving the single-bonded oxygen shifts the C=O vibrations to higher frequencies. Apparently, the conjugation interferes with possible resonance with the carbonyl group, leading to an increase in the absorption frequency for the C=O band.

In the spectrum of vinyl acetate (Fig. 2.49), the C=O band appears at 1762 cm\(^{-1}\), an increase of 25 cm\(^{-1}\) above a normal ester. Notice that the C=C absorption intensity is increased in a manner similar to the pattern obtained with vinyl ethers (Section 2.13). The substitution of an aryl group on the oxygen would exhibit a similar pattern.
Figure 2.52 shows the general effect of $\alpha,\beta$ unsaturation or aryl substitution and conjugation with oxygen on the C=O vibrations.

**Hydrogen-Bonding Effects.** When intramolecular (internal) hydrogen bonding is present, the C=O is shifted to a lower frequency, as predicted in Section 2.14A (p. 56) and shown in the spectrum of methyl salicylate (Fig. 2.51).

**Cyclic Esters (Lactones).** The C=O vibrations are shifted to higher frequencies with decreasing ring size, as predicted in Section 2.14A (p. 55). The unstrained, six-membered cyclic ester $\delta$-valerolactone absorbs at about the same value as a noncyclic ester (1735 cm$^{-1}$). Because of increased angle strain, $\gamma$-butyrolactone absorbs at about 35 cm$^{-1}$ higher than $\delta$-valerolactone.

**F I G U R E 2.52** The effect of $\alpha,\beta$ unsaturation or aryl substitution and conjugation with oxygen on the C=O vibrations in noncyclic (acyclic) esters.
Table 2.8 presents some typical lactones together with their C=O stretching absorption values. Inspection of these values reveals the influence of ring size, conjugation with a carbonyl group, and conjugation with the single-bond oxygen.

**α-Halo Effects.** Halogenation on the α carbon leads to an increase in the C=O frequency.

**α-Keto Esters.** In principle, one should see two carbonyl groups for a compound with “ketone” and “ester” functional groups. Usually, one sees a shoulder on the main absorption band near 1735 cm\(^{-1}\) or a single broadened absorption band.

\[
\text{O} \quad \text{C} \quad \text{O} \\
\text{R} \quad \text{C} \quad \text{C} \quad \text{O} \quad \text{R}
\]

**β-Keto Esters.** Although this class of compounds exhibits tautomerization like that observed in β-diketones (p. 61), less evidence exists for the enol form because β-keto esters do not enolize to as great an extent. β-Keto esters exhibit a strong-intensity doublet for the two carbonyl groups at about 1720 and 1740 cm\(^{-1}\) in the “keto” tautomer, presumably for the ketone and ester C=O groups. Evidence for the weak-intensity C=O band in the “enol” tautomer (often a doublet) appears at about 1650 cm\(^{-1}\). Because of the low concentration of the enol tautomer, one generally cannot observe the broad O–H stretch that was observed in β-diketones.

C—I Stretching Vibrations in Esters. Two (or more) bands appear for the C—I stretching vibrations in esters in the range from 1300 to 1000 cm\(^{-1}\). Generally, the C—I stretch next to the carbonyl group (the “acid” side) of the ester is one of the strongest and broadest bands in the spectrum. This absorption appears between 1300 and 1150 cm\(^{-1}\) for most common esters; esters of aromatic acids absorb nearer the higher-frequency end of this range, and esters of saturated acids absorb nearer the lower-frequency end. The C—I stretch for the “alcohol” part of the ester may appear as a weaker band in the range from 1150 to 1000 cm\(^{-1}\). In analyzing the 1300- to 1000-cm\(^{-1}\) region to confirm an ester functional group, do not worry about fine details. It is usually sufficient to find at least one very strong and broad absorption to help identify the compound as an ester.

F. Amides

Amides show a very strong band for the C=O group that appears in the range of 1680–1630 cm\(^{-1}\). The N—H stretch is observed in the range of 3475–3150 cm\(^{-1}\). Unsubstituted (primary) amides, \(R—CO—NH_2\), show two bands in the N—H region, while monosubstituted (secondary) amides, \(R—CO—NH—R\), show only one band. The presence of N—H bands plus an unusually low value for the C=O would suggest the presence of an amide functional group. Disubstituted (tertiary) amides, \(R—CO—NR_2\), will show the C=O in the range of 1680–1630 cm\(^{-1}\), but will not show an N—H stretch.

### Spectral Analysis Box

**AMIDES**

- **C=O** Stretch occurs at approximately 1680–1630 cm\(^{-1}\).
- **N—H** Stretch in primary amides (—NH\(_2\)) gives two bands near 3350 and 3180 cm\(^{-1}\). Secondary amides have one band (—NH) at about 3300 cm\(^{-1}\).
- **N—H** Bending occurs around 1640–1550 cm\(^{-1}\) for primary and secondary amides.

**Examples:** propionamide (Fig. 2.53) and N-methylacetamide (Fig. 2.54).

![Figure 2.53](image-url) The infrared spectrum of propionamide (Nujol mull, KBr plates). Dots indicate the Nujol (mineral oil) absorption bands (see Fig. 2.8).
2.14 Carbonyl Compounds

**DISCUSSION SECTION**

**Carbonyl Absorption in Amides.** Primary and secondary amides in the solid phase (potassium bromide pellet or Nujol) have broad C=O absorptions in the range from 1680 to 1630 cm\(^{-1}\). The C=O band partially overlaps the N–H bending band which appears in the range 1640–1620 cm\(^{-1}\), making the C=O band appear as a doublet. In very dilute solution, the band appears at about 1690 cm\(^{-1}\). This effect is similar to that observed for carboxylic acids, in which hydrogen bonding reduces the frequency in the solid state or in concentrated solution. Tertiary amides, which cannot form hydrogen bonds, have C=O frequencies that are not influenced by the physical state and absorb in about the same range as do primary and secondary amides (1680–1630 cm\(^{-1}\)).

![Infrared Spectrum of N-Methylacetamide](image)

**Figure 2.54** The infrared spectrum of N-methylacetamide (neat liquid, KBr plates).

![Diagram of Carbonyl Compounds](image)

**Cyclic amides (lactams)** give the expected increase in C=O frequency for decreasing ring size, as shown for lactones in Table 2.8.

![Diagram of Cyclic Amides](image)

**N–H and C–N Stretching Bands.** A pair of fairly strong N–H stretching bands appears at about 3350 cm\(^{-1}\) and 3180 cm\(^{-1}\) for a primary amide in the solid state (KBr or Nujol). The 3350- and 3180-cm\(^{-1}\) bands result from the asymmetric and symmetric vibrations, respectively (Section 2.3). Figure 2.53 shows an example, the spectrum of propionamide. In the solid state, secondary amides and lactams give one band at about 3300 cm\(^{-1}\). A weaker band may appear at about 3100 cm\(^{-1}\) in secondary amides; it is attributed to a Fermi resonance overtone of the 1550-cm\(^{-1}\) band. A C–N stretching band appears at about 1400 cm\(^{-1}\) for primary amides.
**N–H Bending Bands.** In the solid state, primary amides give strong bending vibrational bands in the range from 1640 to 1620 cm\(^{-1}\). They often nearly overlap the C=O stretching bands. Primary amides give other bending bands at about 1125 cm\(^{-1}\) and a very broad band in the range from 750 to 600 cm\(^{-1}\). Secondary amides give relatively strong bending bands at about 1550 cm\(^{-1}\); these are attributed to a combination of a C–N stretching band and an N–H bending band.

### G. Acid Chlorides

Acid chlorides show a very strong band for the C=O group that appears in the range of 1810–1775 cm\(^{-1}\) for aliphatic acid chlorides. Acid chloride and anhydrides are the most common functional groups that have a C=O appearing at such a high frequency. Conjugation lowers the frequency.

**SPECTRAL ANALYSIS BOX**

#### ACID CHLORIDES

- **C=O** Stretch occurs in the range 1810–1775 cm\(^{-1}\) in unconjugated chlorides. Conjugation lowers the frequency to 1780–1760 cm\(^{-1}\).
- **C–Cl** Stretch occurs in the range 730–550 cm\(^{-1}\).

**Examples:** acetyl chloride (Fig. 2.55) and benzoyl chloride (Fig. 2.56).

---

**FIGURE 2.55** The infrared spectrum of acetyl chloride (neat liquid, KBr plates).

**FIGURE 2.56** The infrared spectrum of benzoyl chloride (neat liquid, KBr plates).
DISCUSSION SECTION

C=O Stretching Vibrations. By far the most common acid halides, and the only ones discussed in this book, are acid chlorides. The strong carbonyl absorption appears at a characteristically high frequency of about 1800 cm\(^{-1}\) for saturated acid chlorides. Figure 2.55 shows the spectrum of acetyl chloride. Conjugated acid chlorides absorb at a lower frequency (1780 to 1760 cm\(^{-1}\)), as predicted in Section 2.14A (p. 54). Figure 2.56 shows an example of an aryl-substituted acid chloride, benzoyl chloride. In this spectrum, the main absorption occurs at 1774 cm\(^{-1}\), but a weak shoulder appears on the higher-frequency side of the C=O band (about 1810 cm\(^{-1}\)). The shoulder is probably the result of an overtone of a strong band in the 1000- to 900-cm\(^{-1}\) range. A weak band is also seen at about 1900 cm\(^{-1}\) in the spectrum of acetyl chloride (Fig. 2.55). Sometimes, this overtone band is relatively strong.

In some aromatic acid chlorides, one may observe another rather strong band, often on the lower-frequency side of the C=O band, which makes the C=O appear as a doublet. This band, which appears in the spectrum of benzoyl chloride (Fig. 2.56) at about 1730 cm\(^{-1}\), is probably a Fermi resonance band originating from an interaction of the C=O vibration, with an overtone of a strong band for aryl-C stretch often appearing in the range from 900 to 800 cm\(^{-1}\). When a fundamental vibration couples with an overtone or combination band, the coupled vibration is called Fermi resonance. The Fermi resonance band may also appear on the higher-frequency side of the C=O in many aromatic acid chlorides. This type of interaction can lead to splitting in other carbonyl compounds as well.

C–Cl Stretching Vibrations. These bands, which appear in the range from 730 to 550 cm\(^{-1}\), are best observed if KBr plates or cells are used. One strong C–Cl band appears in the spectrum of acetyl chloride. In other aliphatic acid chlorides, one may observe as many as four bands due to the many conformations that are possible.

H. Anhydrides

Anhydrides show two strong bands for the C=O groups. Simple alkyl-substituted anhydrides generally give bands near 1820 and 1750 cm\(^{-1}\). Anhydrides and acid chlorides are the most common functional groups that have a C=O peak appearing at such a high frequency. Conjugation shifts each of the bands to lower frequencies (about 30 cm\(^{-1}\) each). Simple five-membered ring anhydrides have bands at near 1860 and 1780 cm\(^{-1}\).

SPECTRAL ANALYSIS BOX

ANHYDRIDES

C=O Stretch always has two bands, 1830–1800 cm\(^{-1}\) and 1775–1740 cm\(^{-1}\), with variable relative intensity. Conjugation moves the absorption to a lower frequency. Ring strain (cyclic anhydrides) moves the absorptions to a higher frequency.

C–O Stretch (multiple bands) occurs in the range 1300–900 cm\(^{-1}\).

Example: propionic anhydride (Fig. 2.57).
**DISCUSSION SECTION**

The characteristic pattern for noncyclic and saturated anhydrides is the appearance of *two strong bands*, not necessarily of equal intensities, in the regions from 1830 to 1800 cm\(^{-1}\) and from 1775 to 1740 cm\(^{-1}\). The two bands result from asymmetric and symmetric stretch (Section 2.3). Conjugation shifts the absorption to a lower frequency, while cyclization (ring strain) shifts the absorption to a higher frequency. The *strong and broad* C–O stretching vibrations occur in the region from 1300 to 900 cm\(^{-1}\). Figure 2.57 shows the spectrum of propionic anhydride.

**2.15 AMINES**

Primary amines, R–NH\(_2\), show two N–H stretching bands in the range 3500–3300 cm\(^{-1}\), whereas secondary amines, R\(_2\)N–H, show only one band in that region. Tertiary amines will not show an N–H stretch. Because of these features, it is easy to differentiate among primary, secondary, and tertiary amines by inspection of the N–H stretch region.

**Examples:** butylamine (Fig. 2.58), dibutylamine (Fig. 2.59), tributylamine (Fig. 2.60), and N-methylaniline (Fig. 2.61).
FIGURE 2.58 The infrared spectrum of butylamine (neat liquid, KBr plates).

FIGURE 2.59 The infrared spectrum of dibutylamine (neat liquid, KBr plates).

FIGURE 2.60 The infrared spectrum of tributylamine (neat liquid, KBr plates).
DISCUSSION SECTION

The N–H stretching vibrations occur in the range from 3500 to 3300 cm\(^{-1}\). In neat liquid samples, the N–H bands are often weaker and sharper than an O–H band (see Fig. 2.6). Amines may sometimes be differentiated from alcohols on that basis. Primary amines, determined as neat liquids (hydrogen bonded), give two bands at about 3400 and 3300 cm\(^{-1}\). The higher-frequency band in the pair is due to the asymmetric vibration, whereas the lower-frequency band results from a symmetric vibration (Section 2.3). In dilute solution, the two free N–H stretching vibrations are shifted to higher frequencies. Figure 2.58 shows the spectrum of an aliphatic primary amine. A low-intensity shoulder appears at about 3200 cm\(^{-1}\) on the low-frequency side of the symmetric N–H stretching band. This low-intensity band has been attributed to an overtone of the N–H bending vibration that appears near 1600 cm\(^{-1}\). The 3200-cm\(^{-1}\) shoulder has been enhanced by a Fermi resonance interaction with the symmetric N–H stretching band near 3300 cm\(^{-1}\). The overtone band is often even more pronounced in aromatic primary amines.

Aliphatic secondary amines determined as neat liquids give one band in the N–H stretching region at about 3300 cm\(^{-1}\), but the band is often vanishingly weak. On the other hand, an aromatic secondary amine gives a stronger N–H band near 3400 cm\(^{-1}\). Figures 2.59 and 2.61 are the spectra of an aliphatic secondary amine and an aromatic secondary amine, respectively. Tertiary amines do not absorb in this region, as shown in Figure 2.60.

In primary amines, the N–H bending mode (scissoring) appears as a medium- to strong-intensity (broad) band in the range from 1640 to 1560 cm\(^{-1}\). In aromatic secondary amines, the band shifts to a lower frequency and appears near 1500 cm\(^{-1}\). However, in aliphatic secondary amines the N–H bending vibration is very weak and usually is not observed. The N–H vibrations in aromatic compounds often overlap the aromatic C=C ring absorptions, which also appear in this region. An out-of-plane N–H bending vibration appears as a broad band near 800 cm\(^{-1}\) for primary and secondary amines. These bands appear in the spectra of compounds determined as neat liquids and are seen most easily in aliphatic amines (Figs. 2.58 and 2.59).

The C–N stretching absorption occurs in the region from 1350 to 1000 cm\(^{-1}\) as a medium to strong band for all amines. Aliphatic amines absorb from 1250 to 1000 cm\(^{-1}\), whereas aromatic amines absorb from 1350 to 1250 cm\(^{-1}\). The C–N absorption occurs at a higher frequency in aromatic amines because resonance increases the double-bond character between the ring and the attached nitrogen atom.
2.16 Nitriles, Isocyanates, Isothiocyanates, and Imines

Nitriles, isocyanates, and isothiocyanates all have sp-hybridized carbon atoms similar to the C=\(\text{C}\) bond. They absorb in the region 2100–2270 cm\(^{-1}\). On the other hand, the C=\(\text{N}\) bond of an imine has an \(sp^2\) carbon atom. Imines and similar compounds absorb near where double bonds appear, 1690–1640 cm\(^{-1}\).

### SPECTRAL ANALYSIS BOX

**NITRILES** \(\text{R} - \text{C} = \text{N}\)

- \(\text{C} = \text{N}\)  
  Stretch is a medium-intensity, sharp absorption near 2250 cm\(^{-1}\). Conjugation with double bonds or aromatic rings moves the absorption to a lower frequency.

**Examples:** butyronitrile (Fig. 2.62) and benzonitrile (Fig. 2.63).

**ISOCYANATES** \(\text{R} - \text{N} = \text{C} - \text{O}\)

- \(\text{N} = \text{C} = \text{O}\)  
  Stretch in an isocyanate gives a broad, intense absorption near 2270 cm\(^{-1}\).

**Example:** benzyl isocyanate (Fig. 2.64).

**ISO THIOCYANATES** \(\text{R} - \text{N} = \text{C} = \text{S}\)

- \(\text{N} = \text{C} = \text{S}\)  
  Stretch in an isothiocyanate gives one or two broad, intense absorptions centering near 2125 cm\(^{-1}\).

**IMINES** \(\text{R}_2\text{C} = \text{N} - \text{R}\)

- \(\text{C} = \text{N}\)  
  Stretch in an imine, oxime, and so on gives a variable-intensity absorption in the range 1690–1640 cm\(^{-1}\).

**Figure 2.62** The infrared spectrum of butyronitrile (neat liquid, KBr plates).
**Infrared Spectroscopy**

**FIGURE 2.63** The infrared spectrum of benzonitrile (neat liquid, KBr plates).

**FIGURE 2.64** The infrared spectrum of benzyl isocyanate (neat liquid, KBr plates).

**DISCUSSION SECTION**

**sp-Hybridized Carbon.** The C=\(\text{N}\) group in a nitrile gives a medium-intensity, sharp band in the triple-bond region of the spectrum (2270 to 2210 cm\(^{-1}\)). The C=C bond, which absorbs near this region (2150 cm\(^{-1}\)), usually gives a weaker and broader band unless it is at the end of the chain. Aliphatic nitriles absorb at about 2250 cm\(^{-1}\), whereas their aromatic counterparts absorb at lower frequencies, near 2230 cm\(^{-1}\). Figures 2.62 and 2.63 are the spectra of an aliphatic nitrile and an aromatic nitrile, respectively. Aromatic nitriles absorb at lower frequencies with increased intensity because of conjugation of the triple bond with the ring. Isocyanates also contain an sp-hybridized carbon atom (R\(-\text{N}=\text{C}=\text{O}\)). This class of compounds gives a broad, intense band at about 2270 cm\(^{-1}\) (Fig. 2.64).

**sp\(^2\)-Hybridized Carbon.** The C=\(\text{N}\) bond absorbs in about the same range as a C=C bond. Although the C=\(\text{N}\) band varies in intensity from compound to compound, it usually is more intense than that obtained from the C=C bond. An oxime (R\(-\text{CH}=\text{N}−\text{O}−\text{H}\)) gives a C=N absorption in the range from 1690 to 1640 cm\(^{-1}\) and a broad O−H absorption between 3650 and 2600 cm\(^{-1}\). An imine (R\(-\text{CH}=\text{N}−\text{R}\)) gives a C=N absorption in the range from 1690 to 1650 cm\(^{-1}\).
2.17 NITRO COMPOUNDS

Nitro compounds show two strong bands in the infrared spectrum. One appears near 1550 cm\(^{-1}\) and the other near 1350 cm\(^{-1}\). Although these two bands may partially overlap the aromatic ring region, 1600–1450 cm\(^{-1}\), it is usually easy to see the NO\(_2\) peaks.

**SPECTRAL ANALYSIS BOX**

**NITRO COMPOUNDS**

- **Aliphatic nitro compounds**: asymmetric stretch (strong), 1600–1530 cm\(^{-1}\); symmetric stretch (medium), 1390–1300 cm\(^{-1}\).
- **Aromatic nitro compounds (conjugated)**: asymmetric stretch (strong), 1550–1490 cm\(^{-1}\); symmetric stretch (strong), 1355–1315 cm\(^{-1}\).

**Examples**: 1-nitrohexane (Fig. 2.65) and nitrobenzene (Fig. 2.66).

**FIGURE 2.65** The infrared spectrum of 1-nitrohexane (neat liquid, KBr plates).

**FIGURE 2.66** The infrared spectrum of nitrobenzene (neat liquid, KBr plates).
DISCUSSION SECTION

The nitro group (NO₂) gives two strong bands in the infrared spectrum. In aliphatic nitro compounds, the asymmetric stretching vibration occurs in the range from 1600 to 1530 cm⁻¹, and the symmetric stretching band appears between 1390 and 1300 cm⁻¹. An aliphatic nitro compound—for example, 1-nitrohexane (Fig. 2.65)—absorbs at about 1550 and 1380 cm⁻¹. Normally, its lower-frequency band is less intense than its higher-frequency band. In contrast with aliphatic nitro compounds, aromatic compounds give two bands of nearly equal intensity. Conjugation of a nitro group with an aromatic ring shifts the bands to lower frequencies: 1550–1490 cm⁻¹ and 1355–1315 cm⁻¹. For example, nitrobenzene (Fig. 2.66) absorbs strongly at 1525 and 1350 cm⁻¹. The nitroso group (R–N=O) gives only one strong band, which appears in the range from 1600 to 1500 cm⁻¹.

2.18 CARBOXYLATE SALTS, AMINE SALTS, AND AMINO ACIDS

This section covers compounds with ionic bonds. Included here are carboxylate salts, amine salts, and amino acids. Amino acids are included in this section because of their zwitterionic nature.

SPECTRAL ANALYSIS BOX

CARBOXYLATE SALTS  \( R\text{–}C\text{–}O^-\text{Na}^+ \)

Asymmetric stretch (strong) occurs near 1600 cm⁻¹; symmetric stretch (strong) occurs near 1400 cm⁻¹.

Frequency of C=O absorption is lowered from the value found for the parent carboxylic acid because of resonance (more single-bond character).

AMINE SALTS  \( \text{NH}_4^+ \text{R-NH}_3^+ \text{R}_2\text{NH}_2^+ \text{R}_3\text{NH}^+ \)

N–H

Stretch (broad) occurs at 3300–2600 cm⁻¹. The ammonium ion absorbs to the left in this range, while the tertiary amine salt absorbs to the right. Primary and secondary amine salts absorb in the middle of the range, 3100–2700 cm⁻¹. A broad band often appears near 2100 cm⁻¹.

N–H

Bend (strong) occurs at 1610–1500 cm⁻¹. Primary (two bands) is asymmetric at 1610 cm⁻¹, symmetric at 1500 cm⁻¹. Secondary absorbs in the range 1610–1550 cm⁻¹. Tertiary absorbs only weakly.

AMINO ACIDS

These compounds exist as zwitterions (internal salts) and exhibit spectra that are combinations of carboxylate and primary amine salts. Amino acids show NH₃⁺ stretch (very broad), N–H bend (asymmetric/symmetric), and COO⁻ stretch (asymmetric/symmetric).

Example: leucine (Fig. 2.67).
2.19 SULFUR COMPOUNDS

Infrared spectral data for sulfur-containing compounds are covered in this section. Included here are single-bonded compounds (mercaptans or thiols and sulfides). Double-bonded S–O compounds are also included in this section.

SPECTRAL ANALYSIS BOX

**Mercaptans (Thiols) R–S–H**

S–H Stretch, one weak band, occurs near 2550 cm\(^{-1}\) and virtually confirms the presence of this group, since few other absorptions appear here.

**Example:** benzenethiol (Fig. 2.68).

**Sulfides R–S–R**

Little useful information is obtained from the infrared spectrum.

**Sulfoxides R–S–O**

S=O Stretch, one strong band, occurs near 1050 cm\(^{-1}\).
Infrared Spectroscopy

**SULFONES**

\[
\text{O} \\
R \quad S \quad R \\
\text{O}
\]

$S=O$  Asymmetric stretch (strong) occurs at $1300$ cm$^{-1}$, symmetric stretch (strong) at $1150$ cm$^{-1}$.

**SULFONYL CHLORIDES**

\[
\text{O} \\
R \quad S \quad Cl \\
\text{O}
\]

$S=O$  Asymmetric stretch (strong) occurs at $1375$ cm$^{-1}$, symmetric stretch (strong) at $1185$ cm$^{-1}$.

*Example:* benzenesulfonyl chloride (Fig. 2.69).

**SULFONATES**

\[
\text{O} \\
R \quad S \quad O \quad R \\
\text{O}
\]

$S=O$  Asymmetric stretch (strong) occurs at $1350$ cm$^{-1}$, symmetric stretch (strong) at $1175$ cm$^{-1}$.

$S-O$  Stretch, several strong bands, occurs in the range $1000$–$750$ cm$^{-1}$.

*Example:* methyl $p$-toluenesulphonate (Fig. 2.70).

**SULFONAMIDES** *(Solid State)*

*O* \[
\text{R} \quad S \quad NH_2 \\
\text{O} \\
\text{O}
\]* \[
\text{R} \quad S \quad NH \quad R \\
\text{O} \\
\text{O}
\]

$S=O$  Asymmetric stretch (strong) occurs at $1325$ cm$^{-1}$, symmetric stretch (strong) at $1140$ cm$^{-1}$.

$N-H$  Primary stretch occurs at $3350$ and $3250$ cm$^{-1}$; secondary stretch occurs at $3250$ cm$^{-1}$; bend occurs at $1550$ cm$^{-1}$.

*Example:* benzenesulfonamide (Fig. 2.71).

**SULFONIC ACIDS** *(Anhydrous)*

\[
\text{O} \\
R \quad S \quad O \quad H \\
\text{O}
\]

$S=O$  Asymmetric stretch (strong) occurs at $1350$ cm$^{-1}$, symmetric stretch (strong) at $1150$ cm$^{-1}$.

$S-O$  Stretch (strong) occurs at $650$ cm$^{-1}$.
**Figure 2.69** The infrared spectrum of benzenesulfonyl chloride (neat liquid, KBr plates).

**Figure 2.70** The infrared spectrum of methyl p-toluenesulphonate (neat liquid, KBr plates).

**Figure 2.71** The infrared spectrum of benzenesulfonamide (Nujol mull, KBr plates). Dots indicate the Nujol (mineral oil) absorption bands (see Fig. 2.8).
2.20 PHOSPHORUS COMPOUNDS

Infrared spectral data for phosphorus-containing compounds are covered in this section. Included here are single-bonded compounds (P–H, P–R, and P–O–R). Double-bonded P=O compounds are also included in this section.

SPECTRAL ANALYSIS BOX

PHOSPHINES RPH₂ R₂PH

P–H  Stretch, one strong, sharp band, at 2320–2270 cm⁻¹.
PH₂  Bend, medium bands, at 1090–1075 cm⁻¹ and 840–810 cm⁻¹.
P–H  Bend, medium band, at 990–885 cm⁻¹.
P–CH₃ Bend, medium bands, at 1450–1395 cm⁻¹ and 1346–1255 cm⁻¹.
P–CH₂⁻ Bend, medium band, at 1440–1400 cm⁻¹.

PHOSPHINE OXIDES R₃P=O Ar₃P=O

P=O  Stretch, one very strong band, at 1210–1140 cm⁻¹.

PHOSPHATE ESTERS (RO)₃P=O

P=O  Stretch, one very strong band, at 1300–1240 cm⁻¹.
R–O  Stretch, one or two strong bands, at 1088–920 cm⁻¹.
P–O  Stretch, medium band, at 845–725 cm⁻¹.

2.21 ALKYL AND ARYL HALIDES

Infrared spectral data for halogen-containing compounds are covered in this section. It is difficult to determine the presence or the absence of a halide in a compound via infrared spectroscopy. There are several reasons for this problem. First, the C–X absorption occurs at very low frequencies, to the extreme right of the spectrum, where a number of other bands appear (fingerprint). Second, the sodium chloride plates or cells that are often used obscure the region where halogens absorb (these plates are transparent only above 650 cm⁻¹). Other inorganic salts, most commonly KBr, can be used to extend the region down to 400 cm⁻¹. Mass spectral methods (Sections 8.7 and 8.8) provide more reliable information for this class of compounds. The spectra of carbon tetrachloride and chloroform are shown in this section. These solvents are often used to dissolve solids for determining spectra in solution.
2.21 Alkyl and Aryl Halides

SPECTRAL ANALYSIS BOX

**FLUORIDES R–F**

C–F

Stretch (strong) at 1400–1000 cm\(^{-1}\). Monofluoroalkanes absorb at the lower-frequency end of this range, while polyfluoroalkanes give multiple strong bands in the range 1350–1100 cm\(^{-1}\). Aryl fluorides absorb between 1250 and 1100 cm\(^{-1}\).

**CHLORIDES R–Cl**

C–Cl

Stretch (strong) in aliphatic chlorides occurs in the range 785–540 cm\(^{-1}\). Primary chlorides absorb at the upper end of this range, while tertiary chlorides absorb near the lower end. Two or more bands may be observed due to the different conformations possible.

Multiple substitution on a single-carbon atom results in an intense absorption at the upper-frequency end of this range: CH\(_2\)Cl\(_2\) (739 cm\(^{-1}\)), HCCl\(_3\) (759 cm\(^{-1}\)), and CCl\(_4\) (785 cm\(^{-1}\)). Aryl chlorides absorb between 1100 and 1035 cm\(^{-1}\).

CH\(_2\)Cl

Bend (wagging) at 1300–1230 cm\(^{-1}\).

**Examples:** carbon tetrachloride (Fig. 2.72) and chloroform (Fig. 2.73).

**BROMIDES R–Br**

C–Br

Stretch (strong) in aliphatic bromides occurs at 650–510 cm\(^{-1}\), out of the range of routine spectroscopy using NaCl plates or cells. The trends indicated for aliphatic chlorides hold for bromides. Aryl bromides absorb between 1075 and 1030 cm\(^{-1}\).

CH\(_2\)Br

Bend (wagging) at 1250–1190 cm\(^{-1}\).

**IODIDES R–I**

C–I

Stretch (strong) in aliphatic iodides occurs at 600–485 cm\(^{-1}\), out of the range of routine spectroscopy using NaCl plates or cells. The trends indicated for aliphatic chlorides hold for iodides.

CH\(_2\)I

Bend (wagging) at 1200–1150 cm\(^{-1}\).

**FIGURE 2.72** The infrared spectrum of carbon tetrachloride (neat liquid, KBr plates).
In this final section, we take a look at a typical background spectrum. The infrared energy beam passes not only through the sample being measured but also through a length of air. Air contains two major infrared-active molecules: carbon dioxide and water vapor. Absorptions from these two molecules are contained in every spectrum. Since the FT-IR is a single-beam instrument (see Section 2.5B and Fig. 2.3B), it cannot remove these absorptions at the same time the sample spectrum is determined. That method is used by double-beam, dispersive instruments (Section 2.5A and Fig. 2.3A). Instead, the FT-IR determines the “background” spectrum (no sample in the path) and stores it in the computer memory. After a sample spectrum is determined, the computer subtracts the background spectrum from that of the sample, effectively removing the air peaks.

Figure 2.74 shows a typical background spectrum as determined by an FT-IR instrument. The two absorptions at 2350 cm\(^{-1}\) are due to the asymmetric stretching modes of carbon dioxide. The groups of peaks centered at 3750 cm\(^{-1}\) and 1600 cm\(^{-1}\) are due to the stretching and bending modes of atmospheric (gaseous) water molecules. The fine structure (spikes) in these absorptions are frequently seen in atmospheric water as well as other small gas-phase molecules, due to superimposed rotational energy level absorptions. In liquids or solids, the fine structure is usually blended together into a broad, smooth curve (see hydrogen bonding in alcohols, Section 2.12). Occasionally, other peaks may show up in the background, sometimes due to chemical coatings on the mirrors and sometimes due to degradation of the optics caused by adsorbed materials. Cleaning the optics can remedy the last situation.

The observed bell-curve shape of the background spectrum is due to differences in the output of the infrared source. The “lamp” has its highest output intensities at the wavelengths in the center of the spectrum and diminished intensities at wavelengths at either end of the spectrum. Because the source has unequal output intensity over the range of wavelengths measured, the FT-IR spectrum of the sample will also have a curvature. Most FT-IR instruments can correct this curvature using a software procedure called *autobaseline*. The autobaseline procedure corrects for imbalances in the source output and attempts to give the spectrum a horizontal baseline.

In solid samples (KBr pellets or dry-film preparations), additional imbalances in the baseline can be introduced due to “light-scattering” effects. Granular particles in a sample cause the source energy to be diffracted or scattered out of the main beam, causing loss of intensity. This scattering is usually greatest at the high-frequency (short-wavelength) end of the spectrum, the region from
